INTRODUCTION
Accidental hypothermia is a condition that everybody may experience and that occur in all seasons and locations. Hypothermia has been a problem in military conflicts and exercises [1]. Reduced core temperature combined with the near skin temperature has been observed among cadets at the Norwegian Military Academy after exposure to multiple stressors [2]. Whether this is due to lowered hypothalamic set-point for core temperature or fatigue of the thermoregulatory responses is not established.

The aim of this study was to investigate the effect of continuous military operations on soldiers’ core temperature and alterations in the set-point, and to evaluate the effect of additional nutrition (6000 kcal/day) [3].

SUBJECT AND METHODS
18 cadets from the Norwegian Military Academy who participated in a 7-day ranger training course were included. Some were withdrawn because of medical causalities. 6 cadets in the experiment group (EG) (BMI: 24.6 ± 1.5 kg/m²) who got 6000 kcal and on day 6 were compared with the control group (CG) (4 cadets, BMI: 24.0 ± 0.7 kg/m²) who got the standard diet containing 750 kcal/day. Heart rate, core and skin temperature were recorded as well as changes in triiodothyronine (T3), thyroxin (T4) and thyroid-stimulating hormone (TSH) concentrations in serum. Body composition was investigated before and immediately after the course (Inbody 720). Statistical analysis was performed with repeated-measure MANOVA (p < 0.05) and paired and related samples t-tests in SPSS (IBM SPSS Statistics 19).

RESULTS
Stress during soldiers training resulted in reduction in rectal temperature (p = 0.029) combined with increased skin temperature. A clear relationship between stress and increased feet temperature in the EG (0.6 ± 2.1 °C) (p = 0.029) was observed. Additional nutrition provided a significant increased effect in core temperature (0.4 °C) compared with the CG. Stress resulted in a reduction in T3 (p = 0.008) but no significant difference for T4 and TSH was observed when compared to the CG. A significant reduction in the bodyweight and fat mass was noted for both groups; p = 9 x 10⁻⁸ and p = 2 x 10⁻⁶, respectively, where EG showed a lower reduction in T3 (p = 0.005) was observed. Additional nutrition provided a significant increased effect in core temperature (0.4 °C) compared with the CG. Stress resulted in a reduction in T3 (p = 0.008), but no significant difference for T4 and TSH was observed when compared to the CG. A significant reduction in the bodyweight and fat mass was noted for both groups; p = 9 x 10⁻⁸ and p = 2 x 10⁻⁶, respectively. Additional nutrition during day 6 was compared with the control group (4 cadets, BMI: 24.0 ± 0.7 kg/m²) who got the standard diet containing 750 kcal/day. Heart rate, core and skin temperature were recorded as well as changes in triiodothyronine (T3), thyroxin (T4) and thyroid-stimulating hormone (TSH) concentrations in serum. Body composition was investigated before and immediately after the course (Inbody 720). Statistical analysis was performed with repeated-measure MANOVA (p < 0.05) and paired and related samples t-tests in SPSS (IBM SPSS Statistics 19).

CONCLUSION
Multiple stressors affect the core and skin temperature with a reduced core temperature combined with an increase in feet temperature.

This may be due to reduced set-point. However, this observation may be due to an increase in vasodilation in response to changes in the concentration of signal molecules and receptors on the target cells. Nutrition may contribute to the difference in core temperature between the two groups, but this impact of physical activity cannot be excluded. Alterations in the Thyroid function may also have led to the reduced core temperature. The loss of fat mass may contribute to increased heat loss due to reduced isolation of the body to the colder environment.

This study suggests that the cadets are more vulnerable to become hypothermic but more protected against frostbite or cold injuries.
